1 Preliminaries and Notation

Definition 1.1 (Time-Series Forecasting Setup)**.** *Let* $\{(\mathbf{x}_i, \mathbf{y}_i)\}_{i=1}^{N}$ *be a dataset of input–output pairs where:*

- $\mathbf{x}_i \in \mathbb{R}^{L \times D_{in}}$ *is a lookback window of length* L *with* D_{in} *input variates.*
- $\mathbf{y}_i \in \mathbb{R}^{H \times D_{out}}$ *is a forecast horizon of length* H *with* D_{out} *target variates.*
- *A point-forecast model produces* $\hat{\mathbf{y}}_i \in \mathbb{R}^{H \times D_{out}}$.

The dataset is partitioned into a training set $\mathcal{D}_{train}$, calibration set $\mathcal{D}_{cal}$ *of size* n, *and* test set $\mathcal{D}_{test}$.

Definition 1.2 (State-Conditional Conformal Predictor — Algorithm)**.** ***Calibration Phase:***

1. *Encode each* $\mathbf{x} \in \mathcal{D}_{cal}$ *to latent state* $\mathbf{s} = f_\theta(\mathbf{x}) \in \mathbb{R}^{d_S}$ *where* $d_S = 5$.
2. *Compute absolute residuals* $r_i = |\mathbf{y}_i - \hat{\mathbf{y}}_i|$ *for all* $i \in \mathcal{D}_{cal}$.
3. *Cluster states via K-Means:* $\{c_i = \kappa(\mathbf{s}_i)\}_{i=1}^{n}$ *where* $c_i \in \{1, \ldots, M\}$ *and* $M \geq 2$.
4. *For each cluster* k *with* $n_k = |\{i \colon c_i = k\}|$ *calibration samples, define* $q_k^{1-\alpha}$ *as:*

$$q_k^{1-\alpha} = Quantile\Big(\{r_i \colon c_i = k\},\ \frac{\lceil (n_k + 1)(1 - \alpha) \rceil}{n_k}\Big)$$

where $Quantile(\cdot, p)$ *returns the* p*-th empirical quantile with interpolation method "higher" (i.e.,* $r_{(\lceil p \cdot n_k \rceil)}$ *in sorted order).*

Prediction Phase:

1. *For a test sample* $\mathbf{x}_{new}$, *compute* $\mathbf{s}_{new} = f_\theta(\mathbf{x}_{new})$ *and point forecast* $\hat{\mathbf{y}}_{new}$.
2. *Assign cluster* $k = \kappa(\mathbf{s}_{new})$.
3. *The prediction interval is* $[\hat{\mathbf{y}}_{new} - q_k^{1-\alpha},\ \hat{\mathbf{y}}_{new} + q_k^{1-\alpha}]$ *(element-wise).*

Remark 1.3 (Code-Path Mapping)**.** *The algorithm above maps to specific lines in* `cissn/conformal/state_conditional.py`*:*

- *Step 3:* `StandardScaler` $\hookrightarrow$ *line 140;* `KMeans.fit` $\hookrightarrow$ *line 141.*
- *Step 4 — quantile computation:* $q_k^{1-\alpha}$ *is computed at lines 161–163 with* `np.quantile(..., method='higher')`.
- *Finite-sample correction* $\lceil (n_k+1)(1-\alpha) \rceil / n_k$ *is implemented at line 161.*
- *The finite-sample corrected quantile level* $q_k^{1-\alpha} = \lceil (n_k+1)(1-\alpha) \rceil / n_k$ *appears at line 161 and is clipped to* $[0, 1.0]$ *at line 162. The clipping is necessary because for* $n_k < 1/\alpha - 1$*, the unclipped level exceeds 1.*

Lemma 1.4 (Finite-Sample Correction Monotonicity)**.** *For* $n_k \geq 1$ *and* $\alpha \in (0,1)$*, let* $m = \lceil (n_k+1)(1-\alpha) \rceil$ *as in line 161 of the code. Then the effective quantile level is* $\min(m/n_k,\ 1.0)$ *(clipping at line 162). The coverage guarantee is:*

$$\mathbb{P}(r_{new} \leq q_k^{1-\alpha}) = \frac{\min(m,\ n_k)}{n_k+1} \ \geq\ \frac{m}{n_k+1} \ \geq\ 1-\alpha,$$

where the final inequality holds provided $m \leq n_k$ *(no clipping), which is equivalent to* $n_k \geq \lceil 1/\alpha \rceil - 1$*. When clipping occurs (*$n_k < \lceil 1/\alpha \rceil - 1$*), coverage equals* $n_k/(n_k+1)$*, which may fall below* $1-\alpha$*.*

Proof. The coverage bound follows from the rank-uniformity argument in Theorem **??**. Clipping at 1.0 replaces m by n_k whenever $m > n_k$. This corresponds to using the maximum calibration residual as the quantile, which yields coverage $n_k/(n_k+1)$. The condition $m \leq n_k$ is equivalent to $\lceil (n_k+1)(1-\alpha) \rceil \leq n_k$, which requires $n_k \geq \lceil 1/\alpha \rceil - 1$ (solving $(n_k+1)(1-\alpha) \leq n_k$). The clipping logic and condition are verified at lines 161–162 and 156–159 respectively. □

2 Theorem 1 — Coverage Guarantee

Theorem 2.1 (SCCP Marginal Coverage)**.** *Let* $\mathcal{D}_{cal} = \{(\mathbf{s}_i, r_i)\}_{i=1}^n$ *be a calibration set. Suppose:*

(A1) The state clustering κ *has been fit on an auxiliary set independent of* $\mathcal{D}_{cal}$ *(or, equivalently,* κ *is a deterministic function of only the* $\{\mathbf{s}_i\}$*, not the* $\{r_i\}$*).*

(A2) For each cluster k*, the residuals* $\{r_i : c_i = k\} \cup \{r_{new}\}$ *are exchangeable random variables.*

(A3) $n_k \geq \lceil 1/\alpha \rceil - 1$ *for the cluster assigned to the test sample.*

Then, for any test sample $(\mathbf{s}_{new}, r_{new})$*:*

$$\mathbb{P}\big(r_{new} \leq q_k^{1-\alpha}\big) \;\geq\; 1-\alpha.$$

Consequently, the overall marginal coverage satisfies $\mathbb{P}(y_{new} \in [\hat{y}_{new} - q_k^{1-\alpha},\ \hat{y}_{new} + q_k^{1-\alpha}]) \geq 1-\alpha$.

Proof. Fix a cluster k and let $\mathcal{R}_k = \{r_i \colon c_i = k\} \cup \{r_{\text{new}}\}$ be the combined set of n_k calibration residuals plus the test residual. By assumption (A2), the $n_k + 1$ elements of $\mathcal{R}_k$ are exchangeable.

Step 1 — Rank uniformity. Under exchangeability, the rank of r_{new} among the n_k+1 values of $\mathcal{R}_k$ is uniformly distributed over $\{1, 2, \ldots, n_k+1\}$. Formally, if we sort $\mathcal{R}_k$ in non-decreasing order as $r_{(1)} \leq r_{(2)} \leq \cdots \leq r_{(n_k+1)}$, then

$$\mathbb{P}(r_{\text{new}} = r_{(j)}) = \frac{1}{n_k+1}, \quad \forall j \in \{1, \ldots, n_k+1\}.$$

Step 2 — Coverage event. Let $m = \lceil (n_k+1)(1-\alpha) \rceil$. The quantile $q_k^{1-\alpha}$ is computed at the effective level $\min(m/n_k,\ 1.0)$ (Lemma **??**). By assumption (A3), $n_k \geq \lceil 1/\alpha \rceil - 1$, which implies $m \leq n_k$ (no clipping). Under this condition, $q_k^{1-\alpha}$ is the m-th order statistic of the n_k calibration residuals, and the event $\{r_{\text{new}} \leq q_k^{1-\alpha}\}$ is exactly the event that r_{new} has rank at most m in the combined set $\mathcal{R}_k$.

Step 3 — Probability bound. Since the rank is uniform:

$$\mathbb{P}(\text{rank}(r_{\text{new}}) \leq m) = \frac{m}{n_k+1} = \frac{\lceil (n_k+1)(1-\alpha) \rceil}{n_k+1} \geq \frac{(n_k+1)(1-\alpha)}{n_k+1} = 1-\alpha.$$

The inequality $\lceil x \rceil \geq x$ for any real x yields the bound.

Step 4 — Marginalization. The overall coverage is the mixture:

$$\mathbb{P}(r_{\text{new}} \leq q_{\kappa(\mathbf{s}_{\text{new}})}^{1-\alpha}) = \sum_{k=1}^{M} \mathbb{P}(\kappa(\mathbf{s}_{\text{new}}) = k) \cdot \mathbb{P}(r_{\text{new}} \leq q_k^{1-\alpha} \mid \kappa(\mathbf{s}_{\text{new}}) = k).$$

Each conditional probability is $\geq 1-\alpha$, and since a convex combination of values each $\geq 1-\alpha$ is itself $\geq 1-\alpha$, the marginal guarantee holds. □

Remark 2.2 (Bound Tightness)**.** *The bound is exact when* $\lceil (n_k+1)(1-\alpha) \rceil = (n_k+1)(1-\alpha)$*, i.e., when* $(n_k+1)(1-\alpha)$ *is integer. For* $n_k \geq \lceil 1/\alpha \rceil - 1$ *(condition A3), the excess coverage above* $1-\alpha$ *is at most* $1/(n_k+1)$*. The code issues a warning at* $n_k < 1/\alpha$ *(line 156–159), which is slightly more conservative than the theoretical threshold* $n_k \geq \lceil 1/\alpha \rceil - 1$ *(difference at most 1 sample). Below this threshold, coverage degrades to* $n_k/(n_k+1)$*, which may fall below* $1-\alpha$*.*

3 Code-Implementation Validation of Theorem 1

This section maps each logical step of the proof to the actual code implementation, confirming that no hidden deviation compromises the theorem.

Exchangeability Assumption (A1)

The K-Means clustering κ is fit *jointly* on the calibration states and residuals via `fit()` (line 117). The clustering is a deterministic function of the states $\{\mathbf{s}_i\}$ (scaled via `StandardScaler`, line 140; fitted via `KMeans.fit`, line 141). **If the same calibration set is used for both clustering and quantile estimation**, assumption (A1) is technically violated because the cluster assignment c_i depends on $\mathbf{s}_i$, which is correlated with r_i through the encoder parameters θ.

Mitigation in the code: Since the clustering is a function only of $\mathbf{s}_i$ (a d_S-dimensional mapping of $\mathbf{x}_i$), not of r_i directly, the information leakage is bounded. Formally, we require the *within-cluster* exchangeability condition $\{r_i\}_{i \in \mathcal{I}_k}$ is exchangeable *conditional on the clustering partition*. For K-Means, this holds approximately when the state-space is well-separated. The `check_exchangeability()` method (line 213) provides an empirical diagnostic: it computes the lag-1 autocorrelation within each cluster. Values $|\mathrm{ACF}(1)| \leq 0.3$ suggest approximate exchangeability.

Quantile Computation

The code at line 161 computes:

$$q_level = \frac{\lceil (n_k + 1) \times (1 - \mathrm{alpha}) \rceil}{n_k},$$

with clipping to [0, 1.0] at line 162 (`min(q_level, 1.0)`). The `np.quantile(..., method='higher')` call at line 90 returns the value $r_{(\lceil q_level \cdot n_k \rceil)}$. When $q_level \leq 1$ (no clipping, guaranteed by condition A3), this is the m-th order statistic where $m = \lceil (n_k + 1)(1 - \alpha) \rceil$, matching Theorem **??**. When $q_level > 1$ (clipped), the quantile is the maximum calibration residual, yielding reduced coverage as analyzed in Lemma **??**.

Multivariate Extension

For multivariate residuals $r_i \in \mathbb{R}^{H \times D_{\text{out}}}$, the strategy "per_feature" (line 86) preserves trailing dimensions and computes per-element quantiles. The coverage guarantee extends element-wise: for each output element j, the proof

applies identically because the per-element residual vector within a cluster satisfies exchangeability under assumption (A2). This provides *marginal* coverage for each element individually, but not simultaneous (joint) coverage across all $H \cdot D_{\text{out}}$ elements. This is a standard limitation of marginal conformal prediction, not specific to SCCP. Correlated features across output dimensions may cause systematic undercoverage of joint intervals; for simultaneous guarantees, strategies such as Bonferroni correction across elements would apply.

Empty-Cluster Fallback

When $n_k = 0$ (line 150), the code falls back to global residuals. This does not break coverage because: (a) the quantile from the full calibration set provides valid coverage at level $1 - \alpha$ (the global set is exchangeable by assumption); (b) this is strictly more conservative than per-cluster calibration because it pools over heterogeneous residual distributions, yielding larger intervals.

Small-Cluster Warning

The warning at line 156 flags $n_k < 1/\alpha$. The theoretical condition for guaranteed coverage is $n_k \geq \lceil 1/\alpha \rceil - 1$ (A3 in Theorem **??**). When n_k falls below this threshold, the effective quantile level m/n_k exceeds 1.0 and is clipped to 1.0 (line 162), yielding $q_k = \max(\text{cal residuals})$. In this regime the coverage bound becomes $n_k/(n_k + 1)$, which is strictly less than $1 - \alpha$ when $n_k < \lceil 1/\alpha \rceil - 1$. For example, $n_k = 5$ with $\alpha = 0.1$ gives coverage $5/6 \approx 0.833 < 0.9$. This is not an algebraic error — the formal guarantee simply requires a minimum cluster size. The code's warning at $n_k < 1/\alpha$ is slightly conservative (one sample earlier than the theoretical breakpoint) to provide a safety margin.

4 Scientific Validity Assessment of Theorem 1

Using the GRADE-inspired evidence assessment framework and bias detection protocols:

Internal Validity

- **Assumption Satisfaction:** (A2) is the critical premise. For time-series data, residuals within a state cluster are *not* guaranteed ex-

changeable due to temporal autocorrelation. The code includes `check_exchangeability()` (line 213) that computes ACF(1) and issues warnings. However, this is a *diagnostic*, not a guarantee. **Risk level:** HIGH. Mitigation: the proof can be weakened to hold approximately with coverage gap bounded by $\rho/(1-\rho)$ where $\rho = \max_k |\mathrm{ACF}(1)_k|$.

- **Cluster Stability:** K-Means depends on initialization (mitigated by fixed `random_state=42`, line 48). Cluster assignments may shift between calibration and test if the state distribution changes (distribution shift). **Risk level:** MODERATE.

- **Data Leakage:** If the calibration residuals are used to tune θ, the exchangeability condition collapses. The code separates training (`train()`), calibration (`calibration and validation`), and test (`test()`) phases. **Risk level:** LOW (properly handled).

Construct Validity

- **Ranking Function Consistency:** The proof assumes that the residual ranking at prediction time is "fresh" and not subject to selection bias from modeling. However, the encoder f_θ is trained to minimize MSE, which centers residuals near zero in-sample. If the calibration set overfits (low training MSE but high test MSE), the calibration quantiles underestimate true uncertainty. **Risk level:** MODERATE. Mitigation: train on $\mathcal{D}_{\text{train}}$ only, calibrate on $\mathcal{D}_{\text{cal}}$, test on $\mathcal{D}_{\text{test}}$ — three-way split enforced in code.

Statistical Conclusion Validity

- **Sample Size Adequacy:** For $n_k = 100$ calibration samples per cluster and $\alpha = 0.1$, coverage is ≥ 0.9 with excess at most $1/101 \approx 0.01$. This is adequate. For $n_k = 9$ (minimum before warning), coverage is $\lceil 10 \times 0.9 \rceil / 10 = 0.9$ but the quantile estimate has high variance.

- **Multiple Testing:** Each element in the forecast tensor (horizon $\times$ output dim) receives its own confidence interval when using "per_feature" strategy. The coverage guarantee holds marginally (for each element individually) but not jointly (simultaneous coverage over all elements). **This is a standard limitation of marginal conformal prediction**, not specific to SCCP.

External Validity (Generalizability)

- The proof assumes the same underlying process generates $\mathcal{D}_{\text{cal}}$ and $\mathcal{D}_{\text{test}}$. Distribution shift (concept drift, regime change) invalidates exchangeability globally. Within-cluster conditioning provides partial robustness because a test sample in a state regime similar to calibration residuals receives appropriate intervals, but new regimes (clusters not seen in calibration) have no valid interval. The K-Means fallback to nearest cluster (line 202) does not address this. **Risk level:** MODERATE-HIGH for time-series with nonstationarity.

GRADE Downgrade Assessment

Factor	**Assessment**	**Downgrade**
Risk of bias (within-cluster exchangeability)	Serious (-1)	The assumption is not emp
Inconsistency	Not applicable	Single proof, no replication
Indirectness	Not downgraded	Proof directly addresses cov
Imprecision	Serious (-1) for small n_k	Coverage guarantee require
Publication bias	Not applicable	

Overall evidence quality: MODERATE. The proof is mathematically sound under its assumptions, but (i) the exchangeability assumption for time-series data within K-Means clusters is not formally verified, and (ii) the coverage guarantee requires the cluster-size condition $n_k \geq \lceil 1/\alpha \rceil - 1$, which may be violated in sparse regimes. The practical coverage gap for small clusters (e.g., $n_k = 5$, $\alpha = 0.1$ giving $P = 5/6 \approx 0.833 < 0.9$) is a real degradation, not merely a variance issue.

5 Theorem 2 — Structured Dynamics Stability

Definition 5.1 (State Transition Function)**.** *The state at time t is computed by the recurrence:*

$$\mathbf{s}_t = A(\theta) \cdot \mathbf{s}_{t-1} + B(\mathbf{x}_t) + \beta \cdot \tanh\left(MLP_\phi(A(\theta) \cdot \mathbf{s}_{t-1} + B(\mathbf{x}_t),\ \mathbf{h}_t)\right) \quad (1)$$

where:

- $A(\theta) \in \mathbb{R}^{5\times 5}$ *is block-diagonal with learned parameters* $\theta = (\alpha_L, \alpha_T, \gamma, \omega, \alpha_R)$,

parameterized via sigmoid gates (encoder lines 70–76):

$$A = \begin{bmatrix} \alpha_L & 0 & 0 & 0 & 0 \\ 0 & \alpha_T & 0 & 0 & 0 \\ 0 & 0 & \gamma c & \gamma s & 0 \\ 0 & 0 & -\gamma s & \gamma c & 0 \\ 0 & 0 & 0 & 0 & \alpha_R \end{bmatrix}$$

with $c = \cos(\omega)$, $s = \sin(\omega)$.

- $B(\mathbf{x}_t) = W_B \cdot GELU(LayerNorm(W_{proj}\mathbf{x}_t + b_{proj})) + b_B$ *is the innovation term (encoder lines 35–41, applied at line 93).*
- $\beta =$ `correction_scale` $\in \mathbb{R}$ *is a learnable scalar initialized to 0.01 (line 47). The* tanh *ensures* $\|correction\|_\infty \leq |\beta|$.

Theorem 5.2 (Structured Dynamics Stability)**.** *Let the parameters be constrained via the sigmoid gates:*

$$\alpha_L \in [\alpha_L^{\min}, \alpha_L^{\max}],\ \alpha_T \in [\alpha_T^{\min}, \alpha_T^{\max}],\ \gamma \in [\gamma^{\min}, \gamma^{\max}],\ \alpha_R \in [0, \alpha_R^{\max}]$$

where the ranges are defined at encoder lines 58–68. Then:

(a) ***BIBO stability.*** *For bounded inputs* $\mathbf{x}_t$ *(guaranteed by normalized data), the state sequence is uniformly bounded: there exists* $C < \infty$ *such that* $\|\mathbf{s}_t\|_2 \leq C$ *for all* t*. Specifically, for the subspace* $\tilde{\mathbf{s}} = (s^{(1)}, s^{(2)}, s^{(3)}, s^{(4)})$*:*

$$\|\tilde{\mathbf{s}}_t\|_2 \leq \max(\alpha_T, \gamma, \alpha_R) \cdot \|\tilde{\mathbf{s}}_{t-1}\|_2 + \left\|\tilde{\mathbf{b}}_t\right\|_2 + \beta\sqrt{4},$$

where $\max(\alpha_T, \gamma, \alpha_R) \leq 1.0$*. The seasonal subspace (*$\gamma \leq 1$*) is norm-preserving (no growth); the trend (*$\alpha_T \leq 0.95$*) and residual (*$\alpha_R \leq 0.4$*) subspaces contract.*

(b) The level component $s_t^{(0)}$ *satisfies, for any* $\alpha_L < 1$ *at the learned value:*

$$|s_t^{(0)}| \leq \frac{\max_\tau |B^{(0)}(\mathbf{x}_\tau)| + \beta}{1 - \alpha_L} + |s_0^{(0)}|.$$

When $\alpha_L = 1.0$ *(sigmoid upper bound), the bound is linear:* $|s_t^{(0)}| \leq (B_{\max} + \beta)\, t + |s_0^{(0)}|$*, which is finite for any finite input length* L*.*

(c) ***Seasonal Lyapunov stability.*** *The rotation matrix* $R(\omega, \gamma) = \gamma \begin{bmatrix} \cos\omega & \sin\omega \\ -\sin\omega & \cos\omega \end{bmatrix}$ *satisfies* $\|R(\omega, \gamma)\|_2 = \gamma \leq 1$*, preserving or contracting the norm of* $(s^{(2)}, s^{(3)})$*.*

Proof. **Part (a) — Subspace contraction.**

Define the sub-state $\tilde{\mathbf{s}}_t = (s_t^{(1)}, s_t^{(2)}, s_t^{(3)}, s_t^{(4)}) \in \mathbb{R}^4$ (trend, seasonal cos, seasonal sin, residual). The dynamics for this subspace are:

$$\tilde{\mathbf{s}}_t = \tilde{A} \cdot \tilde{\mathbf{s}}_{t-1} + \tilde{\mathbf{b}}_t + \beta \cdot \tilde{\mathbf{c}}_t$$

where $\tilde{A} = \mathrm{diag}(\alpha_T, R(\omega, \gamma), \alpha_R)$ is the submatrix of A, $\tilde{\mathbf{b}}_t$ is the corresponding innovation subvector, and $\|\tilde{\mathbf{c}}_t\|_\infty \leq 1$ due to tanh.

The spectral radius of $\tilde{A}$ is:

$$\rho(\tilde{A}) = \max(\alpha_T, \gamma \cdot \max(|\cos\omega + i\sin\omega|, |\cos\omega - i\sin\omega|), \alpha_R)$$

Since the rotation matrix $R(\omega, \gamma) = \gamma \begin{bmatrix} \cos\omega & \sin\omega \\ -\sin\omega & \cos\omega \end{bmatrix}$ has singular values $\{\gamma, \gamma\}$ and spectral norm $\|R\|_2 = \gamma$, and the eigenvalues are $\gamma e^{\pm i\omega}$ with magnitude $|\gamma e^{\pm i\omega}| = \gamma$, we have:

$$\left\|\tilde{A}\right\|_2 = \max(\alpha_T, \gamma, \alpha_R)$$

From the sigmoid gates (lines 61–68):

$$\alpha_T^{\max} = 0.95, \quad \gamma^{\max} = 1.0, \quad \alpha_R^{\max} = 0.4$$

Thus $\rho_{\text{sub}} = \max(0.95, 1.0, 0.4) = 1.0$. The seasonal rotation can achieve eigenvalue magnitude 1.0 when $\gamma = 1.0$ (sigmoid upper bound, line 65).

Revised stability argument. The subspace contraction bound above is insufficient because γ can approach 1.0, making $\rho_{\text{sub}} = 1.0$. However, the seasonal component undergoes pure rotation without growth: $\|R(\omega, \gamma)\|_2 = \gamma \leq 1$. The trend component contracts at rate ≤ 0.95. The residual component contracts at rate ≤ 0.4. The *only* non-contracting dimension is the seasonal subspace, and it is norm-preserving (not expanding). Therefore, for the sub-state $\tilde{\mathbf{s}}_t$:

$$\|\tilde{\mathbf{s}}_t\|_2 \leq \alpha_T \cdot |s_t^{(1)}| + \gamma \cdot \left\|(s_t^{(2)}, s_t^{(3)})\right\|_2 + \alpha_R \cdot |s_t^{(4)}| + \left\|\tilde{\mathbf{b}}_t\right\|_2 + \beta$$

Since $\max(\alpha_T, \gamma, \alpha_R) \leq 1$ and innovation/correction terms are bounded (input $\mathbf{x}_t$ is from normalized data), the sequence is bounded. A formal Lyapunov function $V(\mathbf{s}) = \|\mathbf{s}\|_2^2$ yields:

$$V(\mathbf{s}_t) - V(\mathbf{s}_{t-1}) \leq -(1 - \alpha_{\max}^2)\, \|\mathbf{s}_{t-1}\|_2^2 + 2\, \|\mathbf{s}_{t-1}\|_2 \cdot \|\mathbf{b}_t + \beta \mathbf{c}_t\|_2 + \|\mathbf{b}_t + \beta \mathbf{c}_t\|_2^2$$

For the worst-case $\alpha_{\max} = 1$ (level + seasonal), the decrease term vanishes, but growth is limited by the innovation/correction bound. The process is discrete-time bounded-input bounded-output (BIBO) stable.

Part (b) — Level component.

The level dynamics decouple:

$$s_t^{(0)} = \alpha_L \cdot s_{t-1}^{(0)} + b_t^{(0)} + \beta \cdot c_t^{(0)}$$

Unfolding the recurrence from $t = 0$ with $s_0^{(0)} = 0$:

$$s_t^{(0)} = \sum_{\tau=0}^{t-1} \alpha_L^{t-1-\tau} \big(b_\tau^{(0)} + \beta \cdot c_\tau^{(0)}\big)$$

With $|\alpha_L| \leq 1$ and bounded innovations ($|b_\tau^{(0)}| \leq B_{\max}$, $|c_\tau^{(0)}| \leq 1$):

$$|s_t^{(0)}| \leq (B_{\max} + \beta) \cdot \sum_{\tau=0}^{t-1} \alpha_L^\tau \leq \frac{B_{\max} + \beta}{1 - \alpha_L}$$

since the geometric series $\sum_{\tau=0}^{\infty} \alpha_L^\tau = 1/(1 - \alpha_L)$ converges for any $\alpha_L < 1$. The bound grows as $\alpha_L \to 1$, reflecting the learned parameter. When $\alpha_L = 1$ (sigmoid upper bound), the sum equals t, giving the linear bound $|s_t^{(0)}| \leq (B_{\max} + \beta)\, t$, which is finite for any finite sequence length L.

Part (c) — Seasonal Lyapunov stability.

The seasonal dynamics are:

$$\begin{bmatrix} s_t^{(2)} \\ s_t^{(3)} \end{bmatrix} = \gamma \begin{bmatrix} \cos\omega & \sin\omega \\ -\sin\omega & \cos\omega \end{bmatrix} \begin{bmatrix} s_{t-1}^{(2)} \\ s_{t-1}^{(3)} \end{bmatrix} + \begin{bmatrix} b_t^{(2)} \\ b_t^{(3)} \end{bmatrix} + \beta \begin{bmatrix} c_t^{(2)} \\ c_t^{(3)} \end{bmatrix}$$

The homogeneous part preserves the norm: $\|R(\omega, \gamma)\mathbf{v}\|_2 = \gamma \|\mathbf{v}\|_2$. When $\gamma = 1$, the orbit is a pure rotation on a circle; with bounded forcing, it stays on a bounded annular region. When $\gamma < 1$, the orbit spirals inward, eventually dominated by the forcing term. □

Remark 5.3 (Implications for Training)**.** *The structured dynamics guarantee that the forward state does not diverge during training. The eigenvalues of A are bounded at ≤ 1 by the sigmoid gates, which promotes gradient stability along the linear recurrent path $\partial s_t / \partial s_{t-1} = A +$ correction Jacobian. However, BIBO stability of the forward pass does not bound gradients through the correction MLP; gradient clipping may still be warranted for the nonlinear path. Unconstrained RNNs require careful gradient management (clipping, spectral normalization) that the structured encoder partially mitigates*

by limiting the linear-path Jacobian norm to ≤ 1. The BIBO stability also ensures that the encoder generalizes to input lengths not seen during training, provided the innovation function $B(\cdot)$ is bounded (guaranteed by the LayerNorm + GELU activation chain at lines 36–39).

6 Code-Implementation Validation of Theorem 2

Parameter Ranges Verification

The sigmoid gate functions (lines 58–68) produce:

$$\begin{aligned}
\alpha_L &= \sigma(\texttt{raw_alpha_L}) \cdot 0.15 + 0.85 \in [0.85, 1.00] \\
\alpha_T &= \sigma(\texttt{raw_alpha_T}) \cdot 0.25 + 0.70 \in [0.70, 0.95] \\
\gamma &= \sigma(\texttt{raw_gamma}) \cdot 0.20 + 0.80 \in [0.80, 1.00] \\
\alpha_R &= \sigma(\texttt{raw_alpha_R}) \cdot 0.40 \in [0.00, 0.40]
\end{aligned}$$

All ranges are correctly implemented. The $\sigma(\cdot) \in (0, 1)$ ensures strict positivity. The minimum values are guaranteed when $\texttt{raw_*} = -\infty$ (effectively 0), and maximum values when $\texttt{raw_*} = +\infty$ (effectively 1).

Transition Matrix Implementation

The `apply_structured_A` method (lines 78–90) exactly multiplies the block-diagonal matrix A from Definition **??**. The seasonal rotation at lines 84–85 computes:

$$\begin{aligned}
s_{\text{out}}^{(2)} &= s_{\text{in}}^{(2)} \cdot \gamma \cos\omega + s_{\text{in}}^{(3)} \cdot \gamma \sin\omega \\
s_{\text{out}}^{(3)} &= s_{\text{in}}^{(2)} \cdot (-\gamma \sin\omega) + s_{\text{in}}^{(3)} \cdot \gamma \cos\omega
\end{aligned}$$

This matches the matrix form. Note: the code uses $\gamma \cos\omega$ and $\gamma \sin\omega$ as pre-computed scalars (lines 74–75), so the product is exact at each step – there is no accumulated numerical error from repeated multiplication.

Correction Boundedness

The correction term at line 96 clips the MLP output via tanh and scales by $\beta = \texttt{correction_scale}$ (initialized to 0.01). Since $\tanh(\cdot) \in (-1, 1)^5$, $\|\text{correction}\|_\infty \leq \beta$ element-wise, and $\|\text{correction}\|_2 \leq \beta\sqrt{5}$. The bound is correct.

Innovation Boundedness Verification

The innovation term at line 93: $B(\mathbf{x}_t) = W_{\text{innovation}} \cdot \text{LayerNorm}(\text{GELU}(W_{\text{proj}}\mathbf{x}_t + b_{\text{proj}})) + b_{\text{innovation}}$. The GELU and LayerNorm are both Lipschitz-continuous and bounded on bounded inputs. For normalized data (standard scaling applied in the data loader), $\|\mathbf{x}_t\|_\infty$ is bounded, so $B(\mathbf{x}_t)$ is uniformly bounded. This confirms the BIBO stability claim.

Appendix: Preliminary Experimental Validation Plan

To empirically validate Theorems 1 and 2 before submission:

1. **Coverage monotonicity test:** For $\alpha \in \{0.01, 0.05, 0.10, 0.20\}$, measure empirical coverage on ETTh1 test set with $n_{\text{cal}} = 500$. Expect coverage $\geq 1-\alpha$ for all α, with excess decreasing as α increases (larger quantile targets are more stable).

2. **Cluster-size scaling:** Vary n_{cal} from 50 to 2000 in log-spaced increments. Plot coverage gap = (empirical coverage) $-$ $(1-\alpha)$. Expect the gap to shrink as $O(1/\sqrt{n_k})$, consistent with quantile estimation consistency.

3. **Autocorrelation sensitivity:** For clusters binned by ACF(1) $\in [0, 0.1), [0.1, 0.3), [0.3, 0.5), [0.5, 1.0]$, measure coverage. Expect degradation only in the high-autocorrelation bin.

4. **State norm boundedness:** Track $\max_t \|\mathbf{s}_t\|_2$ across 1000 random training batches and verify it stays below the theoretical bound. Test on adversarial inputs (large-norm Gaussian noise) to stress-test the BIBO guarantee.

5. **Seasonal orbit boundedness:** Train on ETTh1 (hourly, strong seasonality). Verify that $\left\|(s_t^{(2)}, s_t^{(3)})\right\|_2$ remains within $[0, C]$ for all time steps and batches.
